

On the relation between low-energy constants and resonance saturation

Abstract

Although there are phenomenological indications that the low-energy constants in the chiral lagrangian may be understood in terms of a finite number of hadronic resonances, it remains unclear how this follows from QCD. One of the arguments usually given is that low-energy constants are associated with chiral symmetry breaking, while QCD perturbation theory suggests that at high energy chiral symmetry is unbroken, so that only low-lying resonances contribute to the low-energy constants. We revisit this argument in the limit of large N_c , discussing its validity in particular for the low-energy constant L_8 , and conclude that QCD may be more subtle than what this argument suggests. We illustrate our considerations in a simple Regge-like model which also applies at finite N_c .

1 Introduction

The low-energy physics of the Goldstone bosons associated with the spontaneous breaking of chiral symmetry is described by the chiral lagrangian, the construction of which is solely based on the general principles of quantum field theory and the symmetries of the underlying fundamental theory of the strong interactions, QCD. The only “dynamical” information present in the chiral lagrangian connecting it to QCD is encompassed by the values of the low-energy constants (LECs) that parameterize the terms appearing in the chiral lagrangian. At lowest order, there are two LECs, the pion decay constant f_π and the quark condensate $\langle\bar{\psi}\psi\rangle$, whereas at higher orders, a growing number of LECs appear. In the theory with three flavors, there are ten physical LECs at order p^4 [1], denoted as L_i , $i = 1, \dots, 10$.

It is thus an interesting question to ask what physics of the strong interaction leads to the values of the LECs observed in nature. Since the physical spectrum contains infinite towers of resonances with given quantum numbers (spin, flavor and parity), it is natural to think of the values of the order p^4 (and higher-order) LECs as resulting from integrating out these resonances [2, 3].¹ In particular, sum rules have been derived relating the order- p^4 constants to the masses and decay constants of these resonances.

Here we revisit in particular the sum rule relating L_8 to the scalar and pseudoscalar resonances with isospin 1, working in the large- N_c and chiral limits. The choice of taking N_c large simplifies the discussion because hadronic resonances are stable in that limit. Furthermore, it is natural to work in the chiral limit, since the LECs are independent of the quark masses. For comparison, we will also discuss the sum rule relating L_{10} to vector and axial-vector resonances with isospin 1.

We begin with reviewing the usual type of sum rule relating L_8 to resonance parameters through the difference of scalar and pseudoscalar two-point functions $\Pi_S(q^2) - \Pi_P(q^2)$, and show that it is in principle ill-defined. We show that the problem originates from the fact that each of these two-point functions is quadratically divergent in QCD. We will then derive a new sum rule, starting from a subtracted dispersion relation, in Sec. 2.2. In Sec. 3 we give an example of how the new sum rule works, using a simple Regge-like model in which the exact answer is known. This model allows us also to consider the situation at finite N_c . In Sec. 4 we test the phenomenological approach in which the difference $\Pi_S(q^2) - \Pi_P(q^2)$ is saturated by a finite number of resonances. The usual argument for this approach is that this difference vanishes in perturbation theory, suggesting that the contribution from resonances higher in the spectrum cancels, at least approximately. Applying this approach to our model, we find that the effective parameters (*i.e.* masses and coupling constants) which are required to fit high-energy constraints as well as to yield the correct value for L_8 are not the same as those of the original infinite spectrum. The final section contains our conclusions.

¹The physics of f_π and $\langle\bar{\psi}\psi\rangle$ is associated with the breaking of chiral symmetry by the vacuum.

2 The large- N_c limit

2.1 Review

In the large- N_c limit, L_8 is given by [4]

$$16B^2L_8 = \Delta\Pi(0) = \frac{1}{2}(\Pi_S(0) - \Pi'_P(0)) , \quad (1)$$

in which the chiral limit is taken, and where we define

$$\Pi_{S,P}(q^2) = i \int d^4x e^{iqx} \langle 0 | T \left\{ J_{S,P}(x) J_{S,P}^\dagger(0) \right\} | 0 \rangle , \quad (2)$$

with $J_S(x) = \bar{d}(x)u(x)$ and $J_P(x) = \bar{d}(x)i\gamma_5 u(x)$. The order- p^2 constant B is equal to $-\langle \bar{\psi}\psi \rangle / f_\pi^2$ in the chiral limit. The prime on $\Pi'_P(0)$ in Eq. (1) indicates that we omit the pion pole present in the pseudoscalar two-point function $\Pi_P(q^2)$. Since the difference $\Pi_S - \Pi_P$ cancels in perturbation theory for vanishing quark masses, this means that $\Delta\Pi(q^2)$ obeys an unsubtracted dispersion relation in the chiral limit, *i.e.*

$$\Delta\Pi(q^2) \equiv \frac{1}{2}(\Pi_S(q^2) - \Pi'_P(q^2)) = \frac{1}{2\pi} \int_0^\infty dt \frac{\text{Im}(\Pi_S(t) - \Pi'_P(t))}{t - q^2 - i\epsilon} . \quad (3)$$

Equation (1) states, then, that L_8 becomes a physical quantity at $N_c = \infty$. In this limit, there is an infinite tower of infinitely narrow resonances in each channel, and we thus have that [5]

$$\begin{aligned} \frac{1}{\pi} \text{Im} \Pi_S(t) &= 2 \sum_n^\infty F_S^2(n) \delta(t - M_S^2(n)) , \\ \frac{1}{\pi} \text{Im} \Pi'_P(t) &= 2 \sum_n^\infty F_P^2(n) \delta(t - M_P^2(n)) . \end{aligned} \quad (4)$$

Use of Eq. (4) in Eq. (3) leads formally to

$$\Delta\Pi(q^2) = \sum_n^\infty \frac{F_S^2(n)}{M_S^2(n) - q^2 - i\epsilon} - \sum_n^\infty \frac{F_P^2(n)}{M_P^2(n) - q^2 - i\epsilon} . \quad (5)$$

In arriving at this expression for $\Delta\Pi(q^2)$, we assumed that the integral over t and the sum over n may be freely interchanged. Ignoring the question of validity of this assumption for the time being, one thus arrives at a sum rule for L_8 :

$$16B^2L_8 = \sum_n^\infty \frac{F_S^2(n)}{M_S^2(n)} - \sum_n^\infty \frac{F_P^2(n)}{M_P^2(n)} . \quad (6)$$

As it stands, this sum rule is not well-defined, because both sums appearing on the right-hand side are quadratically divergent. First, let us give an example. If we assume

Regge-like behavior asymptotically for large n , with²

$$\begin{aligned} M_{S,P}^2(n) &\sim n\Lambda^2, \quad n \text{ large}, \\ F_{S,P}^2(n) &\sim \kappa\Lambda^2 M_{S,P}^2(n), \end{aligned} \quad (7)$$

with Λ a constant of order 1 GeV, and κ is equal to the coefficient of the parton model logarithm, then Eq. (6) looks like

$$16B^2L_8 \sim \kappa\Lambda^2 \left(\sum_n^\infty 1 - \sum_n^\infty 1 \right), \quad (8)$$

which is clearly ill-defined. However, as we will now discuss, the problem is model independent. We will return to the model (7) in Sec. 3.

In order to proceed in the general case, let us introduce cutoffs $N_{S,P}$ on the summation index n in the scalar and pseudoscalar channels, corresponding to cutoffs $M_S(N_S), M_P(N_P)$ on the masses, in order to regulate the sums. Furthermore, we require that both two-point functions match on to QCD perturbation theory for asymptotically large euclidean $Q^2 = -q^2$. In particular, the leading large- Q^2 behavior is given by $\kappa Q^2 \log Q^2$, with κ a constant common to both channels, because the perturbative expressions for scalar and pseudoscalar two-point functions, valid for asymptotically large Q^2 , are equal. It follows that indeed the number of resonances in each channel has to be infinite [5]. Furthermore, writing

$$F_{S,P}^2(n) = f_{S,P}^2(n) M_{S,P}^2(n), \quad (9)$$

each of the sums in Eq. (5) can be written as (omitting the indices S or P)

$$\begin{aligned} \sum_n^N \frac{F^2(n)}{M^2(n) + Q^2} &= \sum_n^N f^2(n) - Q^2 \sum_n^N \frac{f^2(n)}{M^2(n) + Q^2} \\ &\sim \int^{M^2(N)} dM^2 \left(\frac{dn}{dM^2} f^2(n) \right) - Q^2 \int^{M^2(N)} dM^2 \left(\frac{dn}{dM^2} f^2(n) \right) \frac{1}{M^2 + Q^2}. \end{aligned} \quad (10)$$

If $(dn/dM^2)f^2(n)$ goes like a constant for large M^2 , the second integral will behave like $\log(M^2(N)/Q^2)$ for $M^2(N) \gg Q^2$, thus yielding the desired parton-model logarithm. As a consequence, the first integral in Eq. (10) is quadratically divergent. Note that $M^2(N) \gg Q^2$ should hold for any Q^2 , and that we thus need to require that $M^2(N) \rightarrow \infty$ when $N \rightarrow \infty$. It follows that the constant κ can be expressed as

$$\kappa \equiv \lim_{n \rightarrow \infty} \frac{dn}{dM_S^2} f_S^2(n) = \lim_{n \rightarrow \infty} \frac{dn}{dM_P^2} f_P^2(n). \quad (11)$$

Furthermore, it also follows that $M_S^2(N_S)/M_P^2(N_P) \rightarrow 1$, to avoid a term linear in Q^2 in $\Pi_S(q^2) - \Pi_P(q^2)$, for $q^2 = -Q^2$.

²For the asymptotic proportionality between decay constants and the masses, see Eq. (11) below.

In fact, we may choose to introduce a common cutoff Λ_{co}^2 on the t integrals in Eq. (5), which implies cutoffs $N_{S,P}$ on the sums over n such that $M_S^2(N_S), M_P^2(N_P) \leq \Lambda_{co}^2$, while $M_S^2(N_S + 1), M_P^2(N_P + 1) > \Lambda_{co}^2$. Using Eq. (9), our regulated sum rule now reads

$$16B^2 L_8(\Lambda_{co}) = \sum_n^{N_S(\Lambda_{co})} f_S^2(n) - \sum_n^{N_P(\Lambda_{co})} f_P^2(n) . \quad (12)$$

This is of course finite, by construction. However, it does not satisfy the basic field-theoretic requirement that physics should be independent of the cutoff, *i.e.* that the relative change in L_8 due to a change in cutoff goes to zero as we take the cutoff to infinity. Mathematically, this requirement translates into

$$L_8(\Lambda_{co}) = L_8 + O\left(\frac{1}{\Lambda_{co}}\right) , \quad (13)$$

where L_8 is the value of the LEC in the limit of infinite cutoff. That Eq. (12) does not in general satisfy this requirement can be seen as follows. When we increase Λ_{co} , both N_S and N_P increase by integer steps when Λ_{co} moves past the next resonance mass in either channel. Suppose that we increase Λ_{co} such that N_S changes by 1 to $N'_S = N_S + 1$, while $N'_P = N_P$ stays the same. This leads to a change ΔL_8 in L_8 equal to

$$\Delta L_8 = \frac{f_S^2(n = N_S + 1)}{16B^2} . \quad (14)$$

We do not at present have enough information about QCD allowing us to conclude that the right-hand side of this equation goes to zero for $\Lambda_{co} \rightarrow \infty$. In fact, it is *not* the case for the Regge-like behavior of Eq. (7), for which $f_S^2(n)$ goes to a constant for large n (*cf.* Eq. (11)). Therefore, we conclude that the sum rule for L_8 as given by Eq. (6), even with the cutoff we introduced to regulate the sums in Eq. (6), is not well-defined.³

2.2 A better sum rule for L_8

Obviously, the invalid step in the derivation of the sum rule (6) is the interchange of the integral over t and the sum over n , as this led to an expression containing the difference of two quadratically divergent sums. We may remedy this problem by starting from a once-subtracted dispersion relation for $\Delta\Pi(q^2)$ [6],

$$\Delta\Pi(q^2 = -Q^2) = \Delta\Pi(0) - \frac{Q^2}{\pi} \int_0^\infty dt \frac{\frac{1}{2} \text{Im}(\Pi_S(t) - \Pi'_P(t))}{t(t + Q^2)} , \quad (15)$$

where again the pion pole has been omitted. Substituting the large- N_c expressions Eq. (4) for the spectral functions, one obtains

$$\Delta\Pi(q^2 = -Q^2) = \Delta\Pi(0) - Q^2 \left(\sum_n^{N_S} \frac{f_S^2(n)}{M_S^2(n) + Q^2} - \sum_n^{N_P} \frac{f_P^2(n)}{M_P^2(n) + Q^2} \right) , \quad (16)$$

³Unless there is an N so that $f_S(n) = f_P(n)$ for all $n > N$.

where we used Eq. (9), and where N_S and N_P are to be taken to infinity. Again we interchanged the integral over t with the sum over n , but now each sum in Eq. (16) is only logarithmically divergent:

$$\sum_n^N \frac{f^2(n)}{M^2(n) + Q^2} \sim \int^{M^2(N)} dM^2 \left(\frac{dn}{dM^2} f^2(n) \right) \frac{1}{M^2 + Q^2} \sim \kappa \log(M^2(N)/Q^2) , \quad (17)$$

(*cf.* Eq. (11)), and therefore a cutoff Λ_{co} needs to be introduced such that $Q^2 \ll \Lambda_{co}^2 \sim M_S^2(N_S) \sim M_P^2(N_P)$. The limit of N_S and N_P to infinity thus has to be taken in a correlated way such that this condition is fulfilled. It follows that the difference in Eq. (16) is finite and unambiguous. Using the fact that $\Delta\Pi(Q^2)$ should vanish for asymptotically large Q^2 , we arrive at a fully regulated sum rule for L_8 , valid in large- N_c QCD:⁴

$$16B^2 L_8 = \Delta\Pi(0) = \lim_{Q^2 \rightarrow \infty} Q^2 \lim_{N_S, N_P \rightarrow \infty} \left(\sum_n^{N_S} \frac{f_S^2(n)}{M_S^2(n) + Q^2} - \sum_n^{N_P} \frac{f_P^2(n)}{M_P^2(n) + Q^2} \right) , \quad (18)$$

where it is understood that the limit $N_S, N_P \rightarrow \infty$ is taken in a correlated way, such that $M_S^2(N_S)/M_P^2(N_P) \rightarrow 1$.

If, as already discussed in Sec. 2.1, we take the number of resonances in each channel to be finite, assuming that there are n_S in the scalar channel and n_P in the pseudoscalar channel below a certain scale s_0 , above which we stipulate that the scalar and pseudoscalar two-point spectral functions exactly cancel, each of the sums in Eq. (18) is finite, and we may take the large- Q^2 limit under the sums, obtaining

$$16B^2 L_8 = \sum_{n=1}^{n_S} f_S^2(n) - \sum_{n=1}^{n_P} f_P^2(n) , \quad (19)$$

i.e. a finite version of Eq. (6). In general, if the difference of the sums in Eq. (18) would be sufficiently convergent, one would be allowed to take the large- Q^2 limit under the sums. However, it is known that the coefficients of the OPE in QCD have anomalous dimensions, implying that logarithmic corrections to the inverse powers of Q^2 appear. This already implies that expanding in $1/Q^2$ under the sums is in general not allowed. In particular, an exact cancellation of the spectral functions above some s_0 cannot occur.

It is instructive to compare our sum rule for L_8 with a similar sum rule for L_{10} , which is related to the difference of the vector and axial-vector two-point functions $\Pi_V(q^2)$ and $\Pi_A(q^2)$ at $q^2 = 0$. The key difference is that in this case each of these two-point functions is only logarithmically divergent to begin with, because of gauge invariance. The vector and axial-vector two-point functions are defined by

$$\Pi_{V,A}^{\mu\nu} = i \int dx e^{iqx} \langle 0 | T \left\{ J_{V,A}^\mu(x) J_{V,A}^{\dagger\nu}(0) \right\} | 0 \rangle = (q_\mu q_\nu - g_{\mu\nu} q^2) \Pi_{V,A}(q^2) , \quad (20)$$

⁴The pion pole does not play any role in this sum rule.

with $J_V^\mu(x) = \bar{d}(x)\gamma_\mu u(x)$ and $J_A^\mu(x) = \bar{d}(x)\gamma_\mu\gamma_5 u(x)$. Perturbation theory tells us that these two-point functions should both behave like $\kappa' \log Q^2$ for asymptotically large Q^2 , with κ' another constant fixed by the parton model logarithm for this case. For large N_c , the spectra look like

$$\begin{aligned} \frac{1}{\pi} \text{Im } \Pi_V(t) &= 2 \sum_n^\infty F_V^2(n) \delta(t - M_V^2(n)) , \\ \frac{1}{\pi} \text{Im } \Pi'_A(t) &= 2 \sum_n^\infty F_A^2(n) \delta(t - M_A^2(n)) , \end{aligned} \quad (21)$$

where again the prime indicates that we omit the pion pole. A line of reasoning similar to that of Sec. 2.1 shows that

$$\kappa' \equiv \lim_{n \rightarrow \infty} \frac{dn}{dM_V^2} F_V^2(n) = \lim_{n \rightarrow \infty} \frac{dn}{dM_A^2} F_A^2(n) . \quad (22)$$

From this it follows that both Π_V and Π'_A are logarithmically divergent, so that no subtraction analogous to that in Eq. (15) is needed. We thus obtain the sum rule

$$\begin{aligned} -4L_{10} &= \frac{1}{2} (\Pi_V(0) - \Pi'_A(0)) \\ &= \lim_{N_V, N_A \rightarrow \infty} \left(\sum_n^{N_V} \frac{F_V^2(n)}{M_V^2(n)} - \sum_n^{N_A} \frac{F_A^2(n)}{M_A^2(n)} \right) , \end{aligned} \quad (23)$$

where the limit $N_V, N_A \rightarrow \infty$ is again taken in a correlated way such that $\Lambda_{co}^2 \sim M_V^2(N_V) \sim M_A^2(N_A)$ [7, 8]. Now, if we increase Λ_{co} such that, say, $N_V \rightarrow N'_V = N_V + 1$ while $N_A \rightarrow N'_A = N_A$, L_{10} changes by $\Delta L_{10} = -F_V^2(n = N_V + 1)/4M_V^2(n = N_V + 1)$. If we assume that $M_V^2(n)$ grows like n (as in Regge-like behavior), we have that $\Delta L_{10} \sim 1/N_V \rightarrow 0$ for $N_V \rightarrow \infty$. This is to be compared with the case of L_8 in Eq. (14).

3 A Regge-like model at finite N_c

Clearly, the infinite sums in Eq. (4) are not well-defined mathematical expressions. However, at finite N_c the Dirac delta distributions should become better behaved, and it is therefore illustrative to consider the case of finite N_c . In order to do this, we will consider a simple Regge-like model. In this model, each scalar resonance will be represented by a pole of the form [9, 10]

$$\frac{2F_S^2(n)}{z\Lambda^2 + M_S^2(n)} , \quad (24)$$

with

$$z = \left(\frac{-q^2 - i\epsilon}{\Lambda^2} \right)^\zeta , \quad \zeta = 1 - \frac{a}{\pi N_c} , \quad (25)$$

and similar for the pseudoscalar resonances, with masses and residues given by

$$\begin{aligned} M_{S,P}^2(n) &= m_{S,P}^2 + n\Lambda^2, \quad n = 0, 1, \dots, \\ F_{S,P}^2(n) &= \kappa\Lambda^2 M_{S,P}^2(n), \end{aligned} \quad (26)$$

with $m_{S,P}$ also of order 1 GeV (*cf.* Eq. (7)). For simplicity, we take the parameters Λ and a the same in both channels. This choice satisfies Eq. (11).

Expanding the denominator of Eq. (24) to leading order in $1/N_c$, there are poles near $q^2 = M_{S,P}^2(n)(1 - ia/N_c)$. Our model thus describes resonances with masses $\sim M_{S,P}(n)$ and decay widths

$$\Gamma_{S,P}(n) \sim aM_{S,P}(n)/N_c. \quad (27)$$

In the limit $N_c \rightarrow \infty$, all resonances are stable. The function (24) has the correct analytic behavior in the complex q^2 plane [9]: it is analytic everywhere on the physical sheet, except for a cut along the positive real axis, starting at $q^2 = 0$ [9]. This model does not include all corrections one expects at finite N_c ; in particular, it does not include the multi-particle continuum starting at $q^2 = 0$ due to coupling of the sources $J_{S,P}$ to pions, which would make L_8 run. However, as we will see below, the included finite- N_c behavior already leads to an interesting observation.

The scalar spectral function for our model is given by (for simplicity, we set the scale Λ equal to one in the rest of this section)⁵

$$\frac{1}{\pi} \text{Im } \Pi_S(t) = \frac{1}{\pi} \sum_{n=0}^{\infty} \frac{2F_S^2(n) (t^\zeta \sin(\zeta\pi) + \epsilon)}{(t^\zeta \cos(\zeta\pi) + M_S^2(n))^2 + (t^\zeta \sin(\zeta\pi) + \epsilon)^2}, \quad (28)$$

which for $N_c \rightarrow \infty$, *i.e.* $\zeta \rightarrow 1$, reproduces Eq. (4). The expression for $\text{Im } \Pi'_P(t)$ is similar. These spectral functions are logarithmically divergent with n , and we thus introduce a cutoff $N \equiv N_S = N_P + c$ with c a finite arbitrary constant, so that $M_S^2(N_S)/M_P^2(N_P) \rightarrow 1$ for $N \rightarrow \infty$.⁶ The difference between the scalar and pseudoscalar spectral functions is well defined, and we have that, starting from the dispersion relation in Eq. (3),

$$\Delta\Pi(0) = \frac{\kappa}{\pi} \int_0^\infty \frac{dt}{t} \sum_{n=0}^{\infty} \left(\frac{(n + m_S^2)t^\zeta \sin(\zeta\pi)}{(t^\zeta \cos(\zeta\pi) + n + m_S^2)^2 + (t^\zeta \sin(\zeta\pi))^2} - (S \rightarrow P) \right), \quad (29)$$

where we set $\epsilon = 0$, which we are allowed to do as long as we keep N_c finite. We may also send N_c to infinity, but in that case we need to keep an infinitesimal ϵ in order to reproduce the Dirac δ -functions of Eq. (4).

⁵Note that we start our sums at $n = 0$, whereas in Sec. 3 of Ref. [6] sums start at $n = 1$.

⁶We may choose $N_S = N_P + c$ with c an arbitrary finite constant because nothing will depend on c in the limit of infinite cutoff [8].

Substituting $y = t^\zeta$ and performing the sum over n , we obtain

$$\begin{aligned}
16B^2L_8 &= \Delta\Pi(0) \\
&= \frac{\kappa}{2i\pi\zeta} \int_0^\infty dy \left(e^{-i\pi\zeta} \psi(ye^{-i\pi\zeta} + m_S^2) - e^{i\pi\zeta} \psi(ye^{i\pi\zeta} + m_S^2) - (S \rightarrow P) \right) \\
&= \frac{\kappa}{2i\pi\zeta} \left[\log \Gamma(ye^{-i\pi\zeta} + m_S^2) - \log \Gamma(ye^{i\pi\zeta} + m_S^2) - (S \rightarrow P) \right]_0^\infty \\
&= \kappa (m_P^2 - m_S^2) ,
\end{aligned} \tag{30}$$

where

$$\psi(z) = \frac{d}{dz} \log \Gamma(z) \tag{31}$$

is the digamma function.⁷ Interestingly, in this simple model, the result is *independent* of N_c , and it is thus also valid for $N_c \rightarrow \infty$.⁸ The technical reason for this is that setting $Q^2 = 0$ in order to obtain L_8 removes the dependence on N_c , which only appears through the exponent ζ . We note that the new sum rule Eq. (18) does apply to our model at finite N_c as well, if one simply replaces Q^2 by $z\Lambda^2$ with z as defined in Eq. (25), and then takes the limit $z \rightarrow \infty$ in Eq. (18).

Let us comment on this result. First, if we calculate L_8 for this simple model using our new sum rule, Eq. (18), we obtain exactly the same result.⁹ Second, a key point in the calculation of Eq. (30) is that we first performed the sum over n , and after that the integral over t . These operations do not commute: if we would interchange the sum and the integral, the result would be different. If we substitute $y = t^\zeta$ in Eq. (29) and integrate term by term over y , we obtain for each term

$$\frac{\kappa}{\pi\zeta} \int_0^\infty dy \frac{(n + m_S^2) \sin(\pi\zeta)}{(y \cos(\pi\zeta) + n + m_S^2)^2 + (y \sin(\pi\zeta))^2} = \kappa , \tag{32}$$

and, restoring Λ , one would thus find that

$$\Pi'_{S-P}(0) = \kappa\Lambda^2 \left(\sum_{n=0}^N 1 - \sum_{n=0}^{N-c} 1 \right) = c\kappa\Lambda^2 . \tag{33}$$

Clearly, the result (33) does not equal the correct result, Eq. (30). Moreover, it depends on the undetermined constant c , *i.e.* on the details of the regulator. If, as in Sec. 2.1, we increase Λ_{co} , c alternates between the values 0 and 1 (taking $m_S^2 < m_P^2$), and the value of $16B^2\Delta L_8$ defined in Eq. (14) between $\kappa\Lambda^2$ and 0. This simple example calculation demonstrates precisely what goes wrong in the derivation of the naive sum rule Eq. (6): as we already noted in Sec. 2.1, that equation is obtained by first performing the t integrals in Eq. (5) (without subtraction), and then the sums over n , thus leading to the difference of two quadratically divergent sums. The derivation of the new sum rule (18) avoids this problem by starting from a subtracted dispersion relation, Eq. (15).

⁷Our explicit calculation refutes the claim of Ref. [11] that L_8 vanishes in this type of model.

⁸We would obtain the same result setting $N_c = \infty$ from the outset, but taking $\epsilon \rightarrow 0$ at the end of the calculation.

⁹This calculation was done in Sec. 4 of Ref. [6].

Figure 1: Plot of y times the function in Eq. (30) with $m_S^2 = (0.8167)^2$, $m_P^2 = (1.083)^2$ and $\zeta = 0.82$, as a function of y in units in which $\Lambda = 1$, with arbitrary units on the vertical axis (solid line). The dashed line is the OPE to leading order.

Finally, we observe that in our model the result is independent of N_c , and thus it is equally valid for infinite as well as finite N_c . In this respect, it is interesting to consider the spectral function at finite N_c , which we plotted in Fig. 1. More precisely, Fig. 1 is a graph of y times the integrand of Eq. (30) as a function of y , for a value of ζ close to unity. We see that the asymptotic behavior predicted by the OPE sets in already before $y = 3$, and that the resonances at higher values are completely “washed out” by their growing decay widths. In contrast, at infinite N_c the same plot would show an infinite sequence of Dirac delta functions, *cf.* Eq. (4). Nevertheless, despite this very big difference in the behavior of the spectral functions at finite and infinite N_c , the value of L_8 is the same in both cases. Even though the perturbative tail cancels out in the difference between the scalar and pseudoscalar channels, L_8 is not saturated by a finite number of resonances in this model. The contribution to the integral in Eq. (30) coming from the region where the asymptotic behavior already sets in is equally important as that from the region where resonances are clearly visible.

Our example model can be made more realistic by including a finite number of resonances in the scalar and pseudoscalar channels below a certain scale s_0 which are not part of the equally-spaced towers of Eq. (24) (so that $m_{S,P}^2 > s_0$). In that case, with $n_{S(P)}$ extra states in the scalar (pseudoscalar) channel, we would obtain

$$16B^2L_8 = \sum_{n=1}^{n_S} f_S^2(n) - \sum_{n=1}^{n_P} f_P^2(n) + \kappa(m_P^2 - m_S^2). \quad (34)$$

This is to be compared to Eq. (19). The extra term in Eq. (34) originates (in our model) from the infinite towers present above s_0 . While we do not know what this extra term will look like in the case of QCD, we do know that at large N_c there is an

infinite number of resonances in each channel. Therefore, the omission of a term like this in Eq. (19) would represent an unknown systematic error in the application of this sum rule to QCD.

While we certainly do not expect our model to be very realistic, it turns out to be interesting to apply it to a numerical example, already in the large- N_c limit. In order to do this, we first want to eliminate the unknown ratio κ/B^2 from Eq. (30). Requiring absence of a $1/Q^2$ term in the OPE expression for $\Delta\Pi(Q^2)$ in this model, one obtains the additional relation [6]¹⁰

$$2B^2 f^2 = \kappa (m_S^2 + m_P^2 - \Lambda^2) (m_P^2 - m_S^2) , \quad (35)$$

where $f = f_\pi$ in the chiral limit. Combining this with Eq. (30), we find

$$L_8 = \frac{1}{8} \frac{f^2}{m_S^2 + m_P^2 - \Lambda^2} . \quad (36)$$

Taking $m_S = 0.98$ GeV, $m_P = 1.3$ GeV, $\Lambda = 1.2$ GeV (determined from the $a_0(1450)$ and $\pi(1800)$) and $f = 87$ MeV, we find $L_8 = 8 \times 10^{-4}$ to be compared with, *e.g.*, $L_8(M_\rho) = 9 \times 10^{-4}$ [16].

Let us again contrast the case of L_8 with that of L_{10} , as we already did at the end of Sec. 2. In a model with an equally-spaced tower of resonances in each channel, one finds for L_{10} [7]

$$-4L_{10} = \kappa' \sum_{n=0}^{\infty} \frac{(m_A^2 - m_V^2)\Lambda^2}{(m_V^2 + n\Lambda^2)(m_A^2 + n\Lambda^2)} , \quad (37)$$

in which $m_{V,A}$ are the lowest masses in the two towers. The key difference is that in this case the contribution from the towers is not only proportional to the difference $m_A^2 - m_V^2$, analogous to the case of L_8 , but also suppressed by inverse powers of the product of these resonance masses. Taking the contribution from the first few resonances in the tower may already be a good approximation. For instance, with $\kappa' = 1/8\pi^2$ and taking $m_V = 0.77$ GeV, $m_A = 1.25$ GeV and $\Lambda = 1.3$ GeV gives $L_{10} = -5.6 \times 10^{-3}$, to be compared with the full sum in Eq. (37) which gives $L_{10} = -7.1 \times 10^{-3}$. The experimental estimate is $L_{10}(M_\rho) = -5.5 \times 10^{-3}$ [16].

4 Saturation with a finite number of resonances

It is often assumed that each spectral function may be approximated by a *finite* sum over resonances up to a certain scale s_0 , and a “perturbative continuum” at values of $t > s_0$. The perturbative continuum then cancels between scalar and pseudoscalar channels, leaving the difference between two finite sums in Eq. (19). In these sums, the decay constants and masses of the resonances are to be considered effective parameters to be fixed by requiring consistency with the low- and high-momentum expansion of the relevant Green’s function, as obtained from the chiral and operator product

¹⁰Here $m_{S,P}$ correspond to the lowest masses in the towers, whereas in Ref. [6] their values were expressed as $\sqrt{m_{S,P}^2 + \Lambda^2}$.

expansions, respectively [2]. In the large- N_c limit, this phenomenological *ansatz* is a rational approximation [13] to QCD Green's functions, known as the Minimal Hadronic Approximation (MHA) [3]. It encompasses vector meson dominance as a particular case.

One may also attempt to use only the high-energy input from the OPE to predict the low-energy constants, which parameterize the low-momentum expansion. Although phenomenologically this assumption seems to work [16], it remains unclear how this follows from QCD. It is also important to be able to control the systematic error associated with this approximation since, in practice, it is very difficult to go beyond the inclusion of one resonance per channel. Furthermore, there are often not enough equations to determine the decay constants and the masses, so that the effective masses are actually guessed from the position of the physical masses.

In order to gain some insight into these questions a model like that in Eqs. (24,26) is useful because it allows for a comparison of the phenomenological *ansatz* with the exact large- N_c results produced by the model. Therefore let us consider the *ansatz*

$$\frac{1}{2} (\Pi_S(q^2) - \Pi_P(q^2))_{MHA} = \frac{\hat{F}_S^2}{Q^2 + \hat{M}_S^2} - \frac{\hat{F}_P^2}{Q^2 + \hat{M}_P^2} - \frac{B^2 f^2}{Q^2}, \quad (38)$$

where $\hat{M}_{S,P}$ and $\hat{F}_{S,P}$ are parameters to be determined. The idea is to use short-distance (OPE) constraints to fix these parameters, and then use their values to predict L_8 from

$$16B^2 L_8 = \frac{\hat{F}_S^2}{\hat{M}_S^2} - \frac{\hat{F}_P^2}{\hat{M}_P^2}. \quad (39)$$

Writing

$$\hat{F}_{S,P}^2 = \hat{f}_{S,P}^2 \hat{M}_{S,P}^2, \quad (40)$$

the leading OPE ($1/Q^2$) constraint is [6]

$$\hat{f}_S^2 \hat{M}_S^2 - \hat{f}_P^2 \hat{M}_P^2 = \frac{\kappa}{2} (m_P^2 - m_S^2) (m_S^2 + m_P^2 - \Lambda^2). \quad (41)$$

With values of $m_{S,P}$ and Λ close enough to 1 GeV, and assuming that $m_P > m_S$, as phenomenology suggests, the right-hand side of this equation is positive. In fact, this is what happens for the values chosen after Eq. (36).

While this one equation is not sufficient to determine the MHA parameters, an interesting observation can already be made: MHA does not coincide with the physical masses and decay constants. Suppose that we look for solutions in which the decay constants take their actual values. In our model, that means $\hat{f}_S^2 = \hat{f}_P^2 = \kappa \Lambda^2$. One immediately concludes that the ordering of the mass parameters comes out reversed, *i.e.* $\hat{M}_S > \hat{M}_P$ while the true ordering is $m_P > m_S$. The mathematical origin of this difference in sign comes from the fact that the model contains an infinite number of resonances.

To investigate MHA in more detail, let us impose that it gives us the right value of L_8 , which adds the relation

$$\hat{f}_S^2 - \hat{f}_P^2 = \kappa (m_P^2 - m_S^2). \quad (42)$$

The lowest resonance masses are relatively well known,¹¹ while the f parameters are much less well known. If one takes the MHA masses as the physical ones, *i.e.* $\hat{M}_S = m_S$ and $\hat{M}_P = m_P$, one can solve for $\hat{f}_S$ and $\hat{f}_P$ to find

$$\begin{aligned}\hat{f}_S^2 &= \frac{1}{2}\kappa(m_P^2 - m_S^2 + \Lambda^2) , \\ \hat{f}_P^2 &= \frac{1}{2}\kappa(m_S^2 - m_P^2 + \Lambda^2) .\end{aligned}\tag{43}$$

These solutions are *very far* from their “real-world” values (which, in our test, are the model values $\hat{f}_S^2 = \hat{f}_P^2 = \kappa\Lambda^2$). Taking the ratio, and using for instance the numerical example discussed at the end of Sec. 3, we find

$$\frac{\hat{f}_P^2}{\hat{f}_S^2} = \frac{m_S^2 - m_P^2 + \Lambda^2}{m_P^2 - m_S^2 + \Lambda^2} \simeq \frac{1}{3} ,\tag{44}$$

instead of 1, which is the actual value. Note that both the low-energy constraint (42) and the high-energy constraint (41) force $\hat{f}_S^2$ to be different from $\hat{f}_P^2$ to the extent that m_S is not equal to m_P . Remarkably, nevertheless, the MHA expression (38) approximates the true function $\Pi_S - \Pi_P$ to within a few percent for all euclidean Q^2 . Similar properties of the Adler function were studied in more detail in Ref. [12].

One may also try an even simpler *ansatz*, in which only one scalar resonance (in addition to the pion) is kept. Solving Eqs. (41) and (42) for $\hat{f}_S^2$ and $\hat{M}_S^2$, we find, using the same numerical example, $\hat{M}_S^2 \simeq 0.63 m_S^2$ and $\hat{f}_S^2 \simeq 0.51 \kappa\Lambda^2$. As before, the MHA values are very different from the real ones, even though the rational approximation to $\Pi_S - \Pi_P$ works again within a few percent for all euclidean Q^2 .

5 Conclusion

In this paper, we revisited the connection of the order- p^4 LEC L_8 to the scalar and pseudoscalar resonance parameters. In Sec. 2.1 we reviewed the fact that a sum rule of the form (6) is generally ill-defined, and showed that this is to be expected on general grounds in QCD. In Sec. 2.2 we derived a better sum rule, Eq. (18), and argued why this new sum rule gives a finite and universal result. Universality follows because each of the sums in Eq. (18) is only logarithmically divergent, with the difference being finite, and thus the precise details of the choice of the cutoffs N_P relative to N_S do not matter, as required by quantum field theory [8]. For instance, increasing N_S to $N_S + 1$ in Eq. (18) does not change L_8 in the limit $N_S \rightarrow \infty$.

Of course, the ill-defined sum rule of Eq. (6) itself is never used in practice, but instead each sum is restricted to a relatively small set of resonances below a scale s_0 with adjustable parameters, as reviewed in Sec. 4. The derivation of such sum rules, in this case Eq. (19), assumes that above a certain scale s_0 the spectral functions $\text{Im } \Pi_S(t)/\pi$ and $\text{Im } \Pi_P(t)/\pi$ are exactly equal. In contrast, our new sum rule, Eq. (18)

¹¹Assuming that the lowest scalar surviving the large- N_c limit is the a_0 with mass 0.98 GeV.

relies only on the fact that Π_S and Π_P become equal for asymptotically large Q^2 in the euclidean regime.

In Ref. [14] it was shown that, by using the theory of Pade approximants [13], there is a mathematically well-defined connection between resonance parameters and LECs in large- N_c QCD. However, this work is not applicable in the case of L_8 because the spectral function defining $\Delta\Pi(q^2)$ is not positive.

The sum rule (19) can approximate the sum rule (18) if the contribution from the resonances above a certain s_0 is very small. However, there appears to be no reason for this to be true in QCD, unless some new mechanism plays a role higher up in the spectrum. A possibility might be that the resonance parameters of S and P states pair up at higher scales, aligning sufficiently fast for higher resonances to almost not contribute to our sum rule, Eq. (18). This scenario of so-called “parity doubling” or “chiral symmetry restoration” has been the subject of much speculation recently, but little to nothing is known to date about its validity [15]. In fact, our simple model demonstrates that this parity doubling in QCD does not follow from the cancellation of the perturbative tail in $\Pi_S - \Pi_P$, and neither does the saturation of L_8 by a finite number of resonances.

Clearly, our new sum rule is less practical if indeed the contribution from resonances above s_0 cannot be ignored. However, ignoring this contribution anyway would obviously introduce an unknown systematic error. In Sec. 3 we showed how the new sum rule works in a simple example, in which an explicit form for the contribution coming from resonances above s_0 can be derived, *cf.* Eq. (34). While Sec. 2, and in particular the sum rule of Eq. (18), apply to QCD in the limit of infinite N_c , our model is defined for any value of N_c . It is semi-realistic in the sense that it has consistent analytic behavior in the whole complex q^2 plane, while it predicts widths which are suppressed like $1/N_c$, but which grow with increasing resonance mass. In particular, we point to Fig. 1, which shows a qualitatively realistic spectral function for the two-point function $\Delta\Pi(q^2)$. Interestingly, the result for L_8 in that model, Eq. (30), is *independent* of N_c . We thus speculate that also at finite N_c our general conclusion, that the region above s_0 cannot be ignored, remains valid.

Phenomenologically, Eq. (39) seems to work quite well [16]. As we have argued in Sec. 4 using our Regge-like model, this may be at the expense of values for the parameters in the rational approximant (38), which substantially deviate from the actual ones representing the lowest resonances, but which produce a very good approximation to the function $\Pi_S - \Pi_P$ over the entire euclidean region in Q^2 . Since we lack precise information on the scalar and pseudoscalar decay constants in the real world, such deviations might go unnoticed. We conclude that, in spite of the fact that the phenomenology of the scalar/pseudoscalar sector looks very reasonable, a deeper understanding of the relation between L_8 and the spectrum in the scalar and pseudoscalar sectors in large- N_c QCD remains an interesting puzzle.
